

Quantifying decay progression of deadwood in Mediterranean mountain forests

Fravolini, Giulia ; Tognetti, Roberto ; Lombardi, Fabio ; Egli, Markus ; Ascher-Jenull, Judith ; Arfaioli, Paola ; Bardelli, Tommaso ; Cherubini, Paolo ; Marchetti, Marco

Abstract: Forests contribute to the sequestration of organic carbon (C). A key role in forest C cycling is played by deadwood. While a broad range of literature on deadwood decay (above-ground) exists, the mechanisms occurring in the transition zone from deadwood to the humus are poorly understood. In particular, scarce information is available on the temporal patterns of wood compounds (such as lignin and cellulose) during decay processes. Our objective was to provide a deeper understanding on deadwood decay in a Mediterranean montane environment by focussing on semi-natural forests of *Fagus sylvatica* L. (beech). The decay process was studied in a field experiment (in the Majella mountains, Apennine Mountains, Italy) among an altitudinal transect at different climatic conditions. Beech wood blocks (mass, cellulose, lignin) having all an equal in size (5 cm × 5 cm × 2 cm) were placed in soil mesocosms to investigate over one year changes in the overall mass, cellulose and lignin content. The sites were along an altitudinal gradient, reflecting different climatic conditions. The effect of exposure (north- vs. south-facing slopes) was also considered. Deadwood, cellulose and lignin dynamics were related to soil parameters (pH, grain size, moisture, temperature) and climate data. Deadwood decayed very fast and followed an exponential trend. The decay rate constants of the deadwood mass significantly (positively) correlated with air temperature and soil moisture: the lower the temperature, the lower the evapotranspiration, the higher the moisture availability, and the higher the decay rates. Lignin decayed more slowly than cellulose, resulting in average decay rate constants (k) between 0.368 and 0.382 y⁻¹. Soil properties and topographic traits (slope and exposure) strongly influenced the decay processes. At south-facing sites (having an altitude < 1300 m a.s.l., above sea level), decay processes were lower owing, most likely, to drier conditions. The climosequence revealed slower beech deadwood decay processes in south- than north-facing sites of these Mediterranean mountains, owing to the drier conditions. In-field mesocosms were useful to define meaningful indicators of warming-induced changes on the linkages between C storage in beech deadwood and decomposition processes as a function of altitude and exposure.

29 **Abstract**

30 Forests contribute to the sequestration of organic carbon (C). A key role in forest C cycling is
31 played by deadwood. While a broad range of literature on deadwood decay (above-ground) exists,
32 the mechanisms occurring in the transition zone from deadwood to the humus are poorly
33 understood. In particular, scarce information is available on the temporal patterns of wood
34 compounds (such as lignin and cellulose) during decay processes.

35 Our objective was to provide a deeper understanding on deadwood decay in a Mediterranean
36 montane environment by focussing on semi-natural forests of *Fagus sylvatica* L. (beech). The decay
37 process was studied in a field experiment (in the Majella mountains, Apennine Mountains, Italy)
38 among an altitudinal transect at different climatic conditions. Beech wood blocks (mass, cellulose,
39 lignin) having all an equal in size (5 cm x 5 cm x 2 cm) were placed in soil mesocosms to
40 investigate over one year changes in the overall mass, cellulose and lignin content. The sites were
41 along an altitudinal gradient, reflecting different climatic conditions. The effect of exposure (north-
42 vs. south-facing slopes) was also considered. Deadwood, cellulose and lignin dynamics were related
43 to soil parameters (pH, grain size, moisture, temperature) and climate data. Deadwood decayed very
44 fast and followed an exponential trend. The decay rate constants of the deadwood mass significantly
45 (positively) correlated with air temperature and soil moisture: the lower the temperature, the lower
46 the evapotranspiration, the higher the moisture availability, and the higher the decay rates. Lignin
47 decayed more slowly than cellulose, resulting in average decay rate constants (k) between 0.368 and
48 0.382 y^{-1} . Soil properties and topographic traits (slope and exposure) strongly influenced the decay
49 processes. At south-facing sites (having an altitude < 1300 m a.s.l., above sea level), decay
50 processes were lower owing, most likely, to drier conditions. The climosequence revealed slower
51 beech deadwood decay processes in south- than north-facing sites of these Mediterranean
52 mountains, owing to the drier conditions. In-field mesocosms were useful to define meaningful
53 indicators of warming-induced changes on the linkages between C storage in beech deadwood and
54 decomposition processes as a function of altitude and exposure.

57

58 **Introduction**

59 The importance of deadwood in forest ecosystems is undeniable, not only in terms of biodiversity it
60 provides, but also in terms of carbon sequestration and emission. Within this context, deadwood is
61 recognised as one of the most important functional and structural components of forest ecosystems
62 (Harmon et al., 1986; Paletto et al., 2012; Marzano et al., 2013), and is considered an indicator of
63 biodiversity conservation (Lassauce et al., 2011) and long-term carbon (C) storage, especially in
64 temperate-cold climate environments (Ravindranath and Ostwald, 2008).

65 Structural characteristics of standing or downed deadwood provide habitats for different species.
66 Habitat provision for organisms such as nesting birds, refuge for rodent species from predation and
67 safe sites for overstory tree regeneration (Harmon and Franklin, 1989; Heinemann and Kitzberger,
68 2006) have all been revealed as important roles of deadwood in natural temperate forests (Gonzalez
69 et al., 2013). Due to its slow decomposition and persistence on the forest floor (Beets et al., 2008),
70 deadwood represents a substantial reservoir of organic C and nutrients in many forest ecosystems
71 (Carmona et al., 2002; Ganjegunte et al., 2004).

72 At the ecosystem scale, variations in the deadwood amount are suggested to occur in relation to
73 forest type, species composition, disturbance regime (natural and anthropogenic) and successional
74 stage (Gonzalez et al., 2013). In particular, coarse woody debris (CWD), considered as standing
75 dead trees, downed woody debris, and stumps, is a critical component of forest ecosystems since it
76 retains essential nutrients, stores water, contributes to soil development and conservation, and
77 provides habitat for plants and animals, insects, fungi and bacteria (Harmon et al., 1986). CWD
78 decay and the related nutrient mineralisation create unique conditions of microsite heterogeneity
79 (Campbell and Laroque, 2007; Fravolini et al., 2016). However, the dynamics of C exchange and

80 storage of the CWD pool remain poorly understood (Harmon et al., 1986; Scheller and Mladenoff,
81 2002).

82 The decomposition process of CWD can take up decades to several centuries (Lombardi et al.,
83 2012; Petrillo et al., 2016), depending on wood characteristics (tree species, dimensions), climate
84 (temperature and moisture; Woodall and Liknes, 2008) and the position on the ground (i.e., contact
85 with the soil; Radtke and Bolstad, 2004). Most of the available information on decay processes
86 refers to CWD as mass (Russell et al., 2015), and almost no data exists on the temporal behaviour
87 of its chemical components such as lignin or cellulose, especially for Mediterranean mountain
88 forests (Fravolini et al., 2016; Lombardi et al., 2013).

89 Contrasting results in CWD decay rates can be explained in part by the methodologies employed or
90 by the different climates in which the studies were performed (Forrester et al., 2012). In moisture-
91 limited regions, decay progression would be expected to be slow, whereas, in relatively wet forests
92 and environments, climate conditions should promote higher decomposition rates (Progar et al.,
93 2000; Chambers et al., 2001). In Alpine forests, Fravolini et al. (2016) have shown an interactive
94 effect of temperature and moisture on decay dynamics. A number of other variables, including
95 wood density, debris size, nutrient content and the contact with the soil surface, may influence
96 decomposition dynamics (Mackensen et al., 2003; Shorohova et al., 2008), as much as micro-
97 environmental factors surrounding the wood.

98 Wood density, that tells how much C the plant allocates into construction costs (Chave et al., 2006),
99 has often been used to describe decay processes (Schwarze et al., 1999; Schäfer, 2002), as being
100 easily measurable (Sollins et al., 1987; Mackensen et al., 2003). This procedure, however, may
101 underestimate decay dynamics (Petrillo et al., 2016) and does not provide quantitative information
102 on the transition phases of chemical components from woody debris to humus form. As proposed
103 by several authors (Lombardi et al., 2013), lignin and cellulose concentrations may be used to better
104 assess decay patterns of CWD associated with specific site characteristics, such as the microclimatic
105 conditions of topsoil and boundary layer.

106 Among broadleaved species, *Fagus sylvatica* L. (beech) is a dominant or co-dominant tree in
107 European deciduous forests. However, the process of decomposition and the changes in deadwood
108 properties for beech over several stages of decomposition has been rarely addressed (Christensen et
109 al., 2005; Kahl, 2008; Müller-Using and Bartsch, 2009; Herrmann et al., 2015). These studies
110 indicate small differences in wood density between decay classes, and attribute variation in
111 decomposition rates of beech deadwood to the uncertainty over the cause of death. In central
112 European beech forests, decomposition time and debris dimension (and species) are considered the
113 most important information needed to develop regional decomposition model (Herrmann et al.,
114 2015). Although beech represents a major forest type also in Mediterranean mountain ecosystems
115 (Nocentini, 2009), decomposition processes of deadwood in these forests have been poorly
116 addressed so far (Lombardi et al., 2013).

117 We focused on early dynamics of deadwood decay in Mediterranean montane beech forests,
118 characterised by a temperate climate. Our principal aims were: i) to determine early decomposition
119 stages in wood blocks of beech under controlled conditions in the forest topsoil, and ii) to quantify
120 the decay rates of its main chemical constituents, i.e., lignin and cellulose. In addition, we related
121 deadwood decay progression to major environmental drivers, i.e., climatic conditions (temperature
122 and precipitation), slope aspects (north- vs. south-facing sites) and soil characteristics (chemical and
123 physical traits). We expected that climate forcing was more effective, accelerating decomposition
124 processes of wood blocks, on south- than north-exposed slopes and at lower than higher altitudes.

125

126 ***Material and Methods***

127 *Study area*

128 The investigation area is located in the Majella National Park (Abruzzo, central Italy; Fig. 1, Table
129 1). The National Park, extending approximately 740 km², was established in 1991. Four study sites
130 were selected along two climosequences (north vs. south-facing slopes). The altitudinal range of
131 both slopes was between 1170 and about 1480 m above sea level (Table 1).

132 The climate of the study area ranges mostly from temperate-oceanic to temperate-oceanic with
133 submediterranean characteristics; the mean annual temperature varies from 14 °C at the valley
134 bottom (around 130 m a.s.l.) to about 3 °C above 2000 m a.s.l., with mean annual precipitation
135 ranging from approximately 700 to 1600 mm (CFS meteo data). The geological substrate is
136 carbonate bedrock at all study sites.

137 The sub-Mediterranean belt between 1000 and 1700 m a.s.l. consists mainly of beech forests,
138 together with downy oak (*Quercus pubescens* Willd., 1805), Turkey oak (*Quercus cerris* L.),
139 different maples (*Acer* spp.), ash species (*Fraxinus* spp.), hop-hornbeam (*Ostrya carpinifolia*
140 Scop.), with the sporadic occurrence of some conifers. The montane area is dominated by almost
141 pure beech semi-natural forests.

142

143 *Experimental approach*

144 At each site of the climosequence, a field experiment using soil mesocosms was set up, following
145 the procedure given in Fravolini et al. (2016); DACH DecAlp project (<https://www.decalp.org>).
146 Mesocosms (10.2 cm in diameter, 20 cm long PVC tubes) were inserted (summer 2014) into the soil
147 and placed >1 m from large trees and >0.5 m from the adjacent mesocosms (Fig. 2). Furthermore,
148 normed wood blocks (2 cm x 5 cm x 5 cm), deriving from the same beech tree, were added onto the
149 soil surface of each of the mesocosms. This strategy was used because the size and geometry of
150 deadwood is supposed to strongly influence the decay mechanisms (Van der Wal et al., 2007). The
151 wood blocks (coarse woody debris, CWD) were sampled after 0, 8, 16 and 52 weeks (Fig. 2),
152 always with 3 replicates for each sampling time and study site. The dry mass of these wood blocks
153 was determined by standard methods (48 h in the oven at 105 °C). The fresh weight and dry mass
154 were determined to assess the density and water content of the wood blocks. The initial dry mass (at
155 the start of the experiment) was obtained from the wood blocks at t_0 . Afterwards, the blocks were
156 stored at -20 °C until further processing.

157

158 *Cellulose and lignin extraction*

159 The samples were air-dried at room temperature, cut-milled to 4 mm (Retsch mill), aliquoted into
160 sterile Falcon tubes (50 mL) and stored at 4°C until further processing. Cellulose extraction started
161 with weighing the powdered samples into Teflon pockets (10 mg) (Leavitt and Danzer, 1993;
162 Fravolini et al., 2016). At first, the samples were washed in a 5% NaOH solution, two times at 60
163 °C. Thereafter, they were washed another three times, using a 7% NaClO₂ solution and 96%
164 CH₃COOH at 60 °C, until the pH was in the range between 4 and 5. This procedure extracts lignin
165 from the wood samples. The pockets were dried in the oven at 50 °C; the cellulose content was
166 determined as the difference between the initial weight and that of dried samples.

167 The total lignin and the Klason lignin, which is insoluble in strong acid (Dence and Lin, 1992),
168 were then measured. The Klason lignin was obtained using a sequential extraction. The method
169 started with the extraction of water-soluble compounds (Dence and Lin, 1992). Ultrapure water (80
170 °C) was added to 1 g of each sample and stirred 3 times (each time 15 min.). After each washing,
171 the samples were centrifuged for 10 min at 4500 rpm, dried in the oven at 80 °C, and washed three
172 times with 5 ml of ethanol. They were centrifuged again (10 min at 4500 rpm) and the supernatant
173 was discarded. Thereafter, ethanol was again added to the sample and then filtered. The filters were
174 dried over night at 60 °C. In a next step, 3 ml of a 72% H₂SO₄ solution were added to 300 mg of the
175 filter cake, stirred, 84 ml of ultrapure water added, and put into the autoclave for 1 h at 120 °C. This
176 solution was filtered into ceramic crucibles and the liquid evaporated at 110 °C. The weight of the
177 lignin in the crucibles was then measured (Klason lignin). The acid-soluble lignin (ASL; Klason,
178 1893) in the filtrate was determined at 205 nm using Cary 50 UV-VIS Spectrophotometer; . The
179 total lignin was finally calculated as the sum of the ASL + Klason lignin. The amount of cellulose
180 and lignin is given as mass (concentration of cellulose and lignin × deadwood mass).

181

182 *Determination of the decay progression*

183 The decay rate can be estimated by the density loss or mass loss of deadwood during a specific time
 184 period (e.g., Busse, 1994; Melin et al., 2009). The decay rate is commonly expressed through a
 185 decay constant, k , which indicates the density loss or mass loss per year. This constant is derived
 186 from a decay model (Harmon, 1986), which can be expressed by a single-negative-exponential
 187 model:

$$188 \quad x_t = x_0 e^{-kt} \quad (1)$$

189 where x_t is the density or mass of wood blocks at a given time (t), and x_0 is the initial density or
 190 mass (Jenny et al., 1949; Olson, 1963).

191 Data obtained from a single decay rate constant may not completely reflect the whole decay
 192 process. In fact, due to the faster decomposition of cellulose, lignin is relatively enriched. Lignin,
 193 however, also decomposes with time. To unravel the decay behaviour of several compounds in
 194 wood blocks, a multiple-exponential model can then be applied (Means et al., 1985; Mackensen et
 195 al., 2003), using the following equation:

$$196 \quad x = x_1 e^{-k_1 t} + x_2 e^{-k_2 t} \dots + x_n e^{-k_n t} \quad (2)$$

198 where x_1, \dots, x_n are partitioned parameters of the components. From this, the half-life of cellulose or
 199 lignin in the CWD can be calculated:

$$200 \quad t_{1/2} = \frac{\ln(\frac{1}{2})}{-k} \quad (3)$$

201 where $t_{1/2}$ is the half-life and k is the decay constant (obtained from the exponential regression
 202 curve).

203 In addition to equation 1, the decay rate constants were estimated on the basis of the mass loss
 204 within the observation period, using an exponential regression approach, automatically displaying a
 205 decay constant.

206

207 *Soil parameters*

208 Soil samples were taken from 0 to 5 cm, inside the mesocosms, then air-dried at room temperature
209 and sieved at 2 mm. Soil pH (H₂O) was determined using a soil:solution ratio of 1:10. Total C and
210 N contents were analysed in dried samples, using a CN analyzer (TruSpec CHN; LECO, Michigan,
211 U.S.A.). Particle-size was assessed following the pipette procedure according to Indorante et al.
212 (1990). Soil bulk density was determined according to Grossman and Reinsch (2002). Humus forms
213 were determined in the field, according to Zanella et al. (2011).

214

215 *Statistical analysis*

216 The statistical analyses were performed using the IBM SPSS Statistics 21 software (IBM, Chicago,
217 IL, USA). The data distribution was tested using a Shapiro Wilk test. If the test indicated a normal
218 distribution of the data, a t-test or an analysis of variance (ANOVA) was then carried out. In the
219 case of non-normal data distribution, the Mann-Whitney (U-test) or Kruskal-Wallis tests were used
220 to detect differences along the altitudinal gradient and, in particular, between the north- and south-
221 facing sites. Considering that some of the datasets showed a non-normal distribution, the Spearman
222 rank correlation coefficient was applied. A correlation analysis was carried out to infer the influence
223 of environmental conditions (soil, climate) on cellulose, lignin and deadwood decay. All the
224 statistical tests were carried out using a level of significance of 0.05.

225

226 **Results**

227 *Decay rates and half-lives*

228 During the one-year study, wood mass, cellulose and lignin changed significantly in all the study
229 sites (Figs. 1, 2 and 3). In all cases, a distinct (wood mass, cellulose and lignin) loss was recorded.
230 The *k*-values of wood blocks, lignin and cellulose were estimated using the single negative
231 exponential model and an exponential regression curve approach from which also a *k*-value can be
232 derived (Table 3). The two calculation procedures (equation 1 and the regression approach)
233 displayed quite similar results with *k*-values for wood blocks, on average, in the range of 0.368 to

234 0.382 y⁻¹. Typically, the minimum k -value of 0.215 y⁻¹ was registered at a south-facing plot and the
235 maximum (0.496 y⁻¹) at a north-facing plot.

236 The biochemical data of wood blocks are reported in Figures 2 and 3. Also here, both calculation
237 procedures displayed similar values. The average k -value for cellulose was between 1.034 and
238 1.130 y⁻¹ and for lignin between 0.205 to 0.210. Consequently, the k -values for lignin were
239 considerably lower than for cellulose and wood blocks.

240 Using the average k -values, the half-life was calculated for deadwood, lignin and cellulose. The
241 deadwood half-life varied (as an average) between 1.82 years (single negative exponential model)
242 and 1.88 years (exponential regression curve approach). The half-life for cellulose averaged 0.61
243 years using the negative exponential model and 0.67 years using the exponential regression
244 approach. For lignin, the calculation of the half-life showed an average between 3.39 (single
245 negative exponential model) and 3.31 (exponential regression curve approach). However, along the
246 altitudinal gradient, the lignin half-life considerably varied (on average) between 1.4 and 55 years;
247 the higher values were found on the south exposure.

248

249 *Effects of environmental parameters on deadwood decay*

250 Environmental traits and soil data are reported in Tables 1 and 2, respectively. The texture of the
251 soils is predominantly sandy at all the studied sites; all soils exhibit neutral pH conditions.

252 The k -values of cellulose correlated with both climatic parameters, such as mean annual
253 precipitation (MAP) or mean annual air temperature (MAAT). The deadwood k -values (Table 4)
254 were related to MAAT, MAP ($p < 0.05$), soil inorganic C, pH, soil moisture and sand content. The
255 lignin k -values correlated with MAAT ($p < 0.05$) and, similarly to wood blocks, to MAP, soil
256 inorganic C, pH, moisture and sand content. The cellulose, lignin and wood blocks showed a good
257 correlation with MAAT, soil moisture and inorganic C and sand content.

258 The Mann-Whitney test indicated that lignin and wood blocks decomposed faster ($p < 0.05$; Table
259 5) at north-facing sites than at south-facing sites. Lignin and deadwood half-lives were subsequently

260 higher on south facing-sites, reaching values of 26 and 3 years at S2, respectively. On north-facing
261 sites, lignin half-life was between 2 and 4 years while deadwood half-life was less than 2 years.
262 Significant correlations between the amount of lignin and MAAT, deadwood amount, and MAP
263 were found.
264 The k -values, and the mass of wood components (deadwood mass and lignin mass) differed
265 significantly between north- and south-facing sites. The Mann-Whitney test indicated that cellulose,
266 lignin and wood blocks decayed significantly ($p < 0.05$; Table 5) faster on north-facing sites. The
267 lignin half-life was, however, higher at the uppermost south-facing site.

268

269 **Discussion**

270 *Wood decomposition rates*

271 The field mesocosms proved to be very useful in assessing and monitoring the initial phases of
272 deadwood decay in a typical beech forest ecosystem of the Apennines. Although the observation
273 period was short (1 year), the experimental approach carried out under ‘standardised’ conditions (as
274 far as possible) enabled the derivation of k -values for cellulose, lignin and deadwood mass of beech.
275 Both approaches to calculate the k -values (single negative exponential model and exponential
276 regression curve approach) gave comparable values.

277 The range of the measured k -values for the deadwood mass varied between 0.215 and 0.481 y^{-1} . The
278 average k -values determined in this study (0.368 to 0.382 y^{-1}) were relatively high. Müller-Using
279 and Bartsch (2009) reported for beech trees in Germany k -values of 0.35 y^{-1} (mean) for bark and
280 0.178 y^{-1} for deadwood (1 to 10 cm in diameter). In our study, the mean k -values were clearly
281 higher than those reported by Hermann et al. (2015) for beech (0.054 y^{-1}), but closer to k -values
282 found by Ricker et al. (2016) in the south-eastern USA for red maple. The high decay rates can be
283 related, among others, to the size of deadwood (Tarasov and Birdsey, 2001); the smaller the size of
284 deadwood, the faster the decomposition rate. Ostrogovic et al. (2015) studied deadwood decay in
285 *Quercus robur* L., *Carpinus betulus* L., *Alnus glutinosa* Gaernt., *Fraxinus angustifolia* L., with a

286 deadwood size between 1 and 7 cm. The overall k -values were 0.182 y^{-1} for *Q. robur*. With a
 287 smaller diameter, the rates were between 0.189 y^{-1} and 0.217 y^{-1} . The same study gave also
 288 changing k -values for *C. betulus* with diameter (from 0.292 y^{-1} with diameter to 0.189 y^{-1}). Johnson
 289 et al. (2014) reported a mean value of 0.095 y^{-1} (mass, volume) for American beech (*Fagus*
 290 *grandifolia* Ehrh.) and Rock et al. (2008) obtained of 0.07 y^{-1} based on the density approach.

291 The exponential decay model approach has been widely used in analysing empirical data and
 292 modelling decomposition rates (Olson, 1963). However, a constant k assumes a constant relative
 293 decomposition rate through time and requires that the decaying material can be treated as a
 294 homogeneous mass, which may not apply to heterogeneous deadwood organic matter (Cornwell
 295 and Weedon, 2014). Indeed, several authors criticised this approach (e.g., Makinen et al., 2006). A
 296 time lag may occur for decomposers to become established (Harmon et al., 2000; Hérault et al.,
 297 2010), because deadwood and soil initially form a loose system, and decay proceeds slowly for
 298 several years, before the rate increases and approximate exponential decay proceeds (Kueppers et
 299 al., 2004; Zielonka, 2006; Lombardi et al., 2013). In our approach, beech wood blocks used were in
 300 contact with the soil since the very beginning of decay. The single exponential model function
 301 nicely described the patterns of initial decomposition stages. If there had been a time lag until
 302 establishment of the organisms that are necessary for the wood decay, then the k -values would be
 303 even higher (which rather seems unrealistic). The observed trend however gives no reason to
 304 assume that such a time lag has occurred. Differences in wood decay between studies can be due to
 305 specific site conditions and species-site combinations, in which the decomposition started. In
 306 nature, a certain proportion of deadwood may stay upright for many years before it falls on the
 307 forest floor (e.g., trees killed by insects). A tree infected by rot fungi may fall down only a few
 308 years after its death and is subject to a much faster decay rate (Stouranet and Rolstad, 2002).

309 Temperature and precipitation were key variables in early stages of deadwood decay (Table 4).
 310 A negative relationship between the decay constant of wood blocks and air temperature was found
 311 in our study. Along the climosequence, the cooler the climate the faster was the decay rate of lignin

(not significant for cellulose and deadwood). In an Alpine environment, Ascher et al. (2012), using a climosequence approach, found evidences that thermal conditions (exposure and altitude) shape soil traits and the microbial community. In Mediterranean mountain environments, lower air temperatures correlate with a higher soil (lower evaporative demand) and wood moisture, higher moisture availability accelerating the decay of organic matter. Saproxylic organisms, including fungi (being inactive with less than 20% humidity), strongly rely on the availability of woody resource to complete their life-cycle and, in turn, on the moisture content of deadwood (Cornelissen et al., 2012; Fukasawa and Matsuoka, 2015). Together with the mild climate, optimal conditions for a fast wood decay are created. Here, moisture availability was probably regulated more by evaporative demand (temperature) than water supply (precipitation). In addition, the k -values of cellulose were not significantly affected by any of the considered explanatory factors.

In-field investigations on the course of decomposition of beech deadwood are scarce (e.g., Ódor et al., 2006; Lombardi et al., 2013), as well as on the process of decomposition at different stages of decay and changes in deadwood properties over time (e.g., Herrmann et al., 2015; Arnstadt et al., 2016). A clear tendency for a rapid initial CWD density loss followed by a stable density phase was a common observation in these studies. Hövemeyer and Schauerermann (2003), investigating the decay of fine woody debris in litterbags (diameter 4.3–11.5 cm) in a beech stand on calcareous soil (Gottingen Forest, Lower Saxony, Germany), observed that 40% and 60% of the wood was decomposed under the litter layer after 2 and 6 years, respectively.

Relationships between decay processes and environmental conditions

Wood blocks progressively showed increasing relative mass loss rates, down to 50–60% mass loss, probably because of the progressive loss of initial heartwood resistances over time (Harmon et al., 1986). Several factors may simultaneously account for the increase in relative decomposition rates from early to intermediate stages of decay. First, leaching of constitutive wood compounds increase progressively with the progress of decay phases (e.g., dissolved organic C, polyphenols; Spears and

338 Lajtha, 2004), as permeability to water and microbial colonization rise, and the highly polymeric
339 wood compounds are degraded into soluble fractions (Harmon et al., 1986). This feature is more
340 pronounced in CWD of high density or in species producing hydrophobic resins (e.g., *Pinus* spp.).
341 Second, as wood decay advances, microbial decomposers gather and accumulate nutrients, limiting
342 microbial growth and activity through a variety of mechanisms (Cornwell et al., 2009). This strong
343 initial nutrient acquisition by microbial decomposers may be progressively reinvested towards
344 lignocellulolytic enzyme production (Sinsabaugh et al., 1993; Weedon et al., 2009). Finally,
345 invertebrate decomposers and microbial activity reduce wood particle size, and the consequently
346 higher surface-to-volume ratio results in faster decomposition (Harmon et al., 1986).
347 Decomposition models can be developed on the basis of species-specific information on
348 decomposition time and debris dimension (Herrmann et al., 2015).

349 Soil neutral and basic conditions (pH), soil moisture and the grain size (i.e., sand content) were
350 major drivers governing decomposition dynamics in these beech forests. However, not all wood
351 compounds responded similarly, i.e., cellulose decayed much faster than lignin. Besides wood
352 characteristics and climatic conditions, also soil traits may influence deadwood decay dynamics
353 (Liu et al., 2013), although, substrate-related parameters have been rarely taken into account (e.g.,
354 van der Wal et al., 2007; Risch et al., 2013). Microbial activity was found higher in the uppermost
355 soil layer, with a reduced soil microbial biomass with increasing soil depth, topsoil being more
356 exposed to shifts in temperature, moisture and organic matter input (Bardelli et al., 2017). Owing to
357 its slower decay rate, lignin can be considered important in stocking organic C in the mid-term and,
358 thus, for ensuring a quite stable background source of organic C in these beech forest soils. Lignin
359 has a higher proportion of C than cellulose (Donnelly et al., 1990), the latter being easily
360 decomposed by microorganisms (Wild et al., 2014). Information on decomposition patterns of
361 foliage and deadwood is still rare. In a simulation and observational exercise in the Swiss Alps,
362 Didion et al. (2014) found remaining C in beech foliage litter after 10 years and in lying dead trees
363 after 14–21 years. In forest C inventories, an accurate estimation of the variability of C pools in

litter, deadwood, and soil remains a major challenge.

The decay rates of cellulose, lignin and deadwood (at the end of the experiment) correlated well with the sand content of forest soils. Sand and inorganic C contents of soils, as well as soil moisture levels, are related to weathering processes and water availability. Decay rates in north-facing sites were higher than in south-facing sites (regardless of the altitude), north-facing sites having probably lower evaporative demand. Bardelli et al. (2017), studying bacterial, fungal and archaeal communities degrading soil organic matter, observed altitude- and enzyme-specific exposure effects along a climosequence in the Italian Alps, with microbial biomass and activity being higher in the north-facing slopes, irrespective of the altitude; hydrolytic enzyme activities declined with decreasing soil moisture. The soil moisture content was lower in south-facing sites (between 30 and 40%) than in the north-facing sites (between 40 and 50%), albeit the similar annual precipitation, probably due to higher evaporative demand. We hypothesize that the moister and cooler conditions gave rise to a more marked weathering at north-facing sites. Moisture availability was found to be a stronger driver of decomposition than temperature or precipitation, when considered alone (Liu et al., 2006). Water availability may add to local topography, soil composition and incoming radiation, shaping the spatial and temporal variation in decomposition rates. Indeed, climatic conditions have a strong impact on wood decomposer communities (Hoppe et al., 2016), soil moisture controlling nutrient availability and oxygen diffusion being essential for microbial decomposition (Skopp et al., 1990).

The present study area has a MAAT of 7-8 °C. Mackensen et al. (2003) found that decay rates increase significantly only at a MAAT above 12-13 °C. These authors observed that, independently from tree species and climatic zones, moisture has a large influence on the maximum rate of decay, in line with our results. Fravolini et al. (2016) showed that, in subalpine and alpine environments, soil traits (including moisture, texture, temperature, and exposure) influence the decay dynamics of deadwood and its components. Considering that the dynamics of decay processes depend on climatic conditions and substrate traits (Harmon et al., 1986; Chambers et al., 2000; Mackensen et

al., 2003), and that beech forests in Europe grow at sites with relatively low MAAT (Bolte et al., 2007), cooler and moister environmental conditions (favorable to fungal decomposers) may generally result in higher decay rates.

The spatial structure of the decomposition environment influenced to a great deal the variation in initial decay rates of beech wood blocks. In a comparative study on different tree species in North America, Yin (1999) concluded that short-term studies often overestimate the importance of site conditions and wood properties for decay rates. The decay model developed by Yin (1999) showed that, with an increase in temperature of 2 °C in January and July, a decrease in wood density of 9–55% was observed in the first year. Over a period of 100 years, however, the rate of decay increased by only 1–14%. While the importance of wood decay for the global carbon balance is widely recognized, surprisingly little is known about its long-term dynamics and its abiotic and biotic drivers (Freschet et al., 2011). Progress in this field is hindered by the long time-scale inherent to the low decay rates of wood, and methods to assess initial decomposition dynamics in standardized in-field conditions may provide the basis for modelling decomposition trajectories in different species-site combinations.

405

406 *Conclusions*

We found that the decay rates of beech wood blocks in montane temperate environments (Apennines) were relatively high. Though our observations were focused on the initial phases of decomposition of relatively small wood blocks, the measured decay rates were comparable to average values observed for CWD of the same species in other sites across Europe. Moreover, cellulose and lignin decay rates over the observation time frame highlighted clear decay patterns. Local scale factors, including soil properties and slope aspect, were effective in influencing the decay dynamics of beech wood blocks and their components. Air temperature and soil moisture had a strong impact on the decay processes: the lower the temperature, the lower the evaporative demand, the higher the moisture availability, and the higher the decay rates. In these Mediterranean

416 montane forest ecosystems, decay processes were slower in south- than north-facing sites owing to
417 the drier conditions. This climosequence approach, using in-field mesocosms, provided important
418 information on the variation in the initial stage of beech deadwood decay as a function of altitude
419 and exposure. Since time series are needed to assess and model the dynamics of deadwood
420 decomposition, long-term monitoring of decay processes and parameter estimates from empirical
421 investigations are required to extrapolate beyond the spatial and temporal scale of data collection.

¹⁾ MAAT: mean annual temperature, ²⁾ Precipitation = annual precipitation, ³⁾ d = diameter; l = length

Figure captions

Fig. 1. Amount of dry mass (weight \pm standard error) of the wood blocks (placed into mesocosms) as a function of time (0 – 52 weeks), site (altitude) and exposure (north vs. south).

Fig. 2. Amount of cellulose (= concentration \times dry mass of wood block; weight \pm standard error) as a function of time (0 – 52 weeks), site (altitude) and exposure (north vs. south).

Fig. 3. Amount of lignin (= concentration \times dry mass of wood block; weight \pm standard error) in the wood blocks as a function of time (0 – 2 years), site (altitude) and exposure (north vs. south).
